Abstract

Electronic states in silicon quantum dots are examined theoretically, taking into account a multivalley structure of the conduction band. We find that (i) exchange interaction hardly works between electrons in different valleys. In consequence electrons occupy the lowest level in different valleys in the absence of Hund's coupling when the dot size is less than 10 nm. High-spin states are easily realized by applying a small magnetic field. (ii) When the dot size is much larger, the electron-electron interaction becomes relevant in determining the electronic states. Electrons are accommodated in a valley, making the highest spin, to gain the exchange energy. (iii) In the presence of intervalley scattering, degenerate levels in different valleys are split. This could result in low-spin states. These spin states in multivalley artificial atoms can be observed by looking at the magnetic-field dependence of peak positions in the Coulomb oscillation.

I. INTRODUCTION

Quantum dots fabricated on semiconductor heterostructures, e.g., GaAs/AlGaAs, are called artificial atoms. The electronic states in such quantum dots have been elucidated by examining the Coulomb oscillation; a peak structure of the current as a function of gate voltage which changes the number of electrons in the dots, N , one by one. In disk-shaped quantum dots, discrete energy levels show an atomic-like shell structure.¹ They are filled consecutively with increasing N . When a shell is partly filled, electrons occupy degenerate energy levels with parallel spins (Hund's rule), as seen in the periodic table of atoms.^{1,2} These properties of the artificial atoms have been quantitatively explained by theoretical studies including the electron-electron Coulomb interaction exactly.^{3,4,5,6,7,8,9}

Compared with the electronic states in GaAs quantum dots, those in silicon (Si) quantum dots have been poorly understood. A combination of microfabrication and oxidation techniques on Si enables to fabricate so small quantum dots as ~ 10 nm.^{10,11,12,13,14,15,16} The Si quantum dots are being extensively studied for their application to single-electron devices working at room temperature. However, the lack of information on the precise shape of individual dots has prevented fundamental researches of the electronic states. Particularly, there have been few theoretical studies which consider the effects of a multivalley structure of the conduction band on the electronic states in Si quantum dots.¹⁷ The multivalley structure should lead to different properties of electronic states from those in GaAs quantum dots with single valley at Γ point.

Recently some experiments of the Coulomb oscillation have been reported for Si quantum dots.^{14,15,16} The magnetic-field dependence of the current peaks indicates various spin states in the quantum dots. Another experiment has implied the observation of the Kondo effect, which might be due to degenerate energy levels by the multivalley structure of the conduction band.¹⁸ The explanation for these phenomena requires the understanding of the electronic states in Si quantum dots. The study of spin states is also important for the application of the quantum dots to "spintronics," quantum computers,¹⁹ etc.

The purpose of the present paper is to elucidate fundamental characters of the electronic states and spin configurations in Si dots, "multivalley artificial atoms," for the first time. We adopt the effective mass approximation,²⁰ assuming that the size of quantum dots is sufficiently larger than the lattice constant, to consider the following properties of Si; (i)

more than one valley of the conduction band (two equivalent valleys in Si-MOS systems and six in the bulk), (ii) anisotropy of the effective mass at a valley ($m_l^* = 0.98m_0$, $m_t^* = 0.19m_0$), and (iii) large Zeeman effect (effective g-factor is $g^* \simeq 2$ in Si, whereas $g^* \simeq 0.4$ in GaAs). We determine the electronic configuration of the ground state, considering Coulomb and exchange interactions. We show that the exchange interaction hardly works between electrons in different valleys. In consequence electrons occupy the lowest level in different valleys in the absence of Hund's coupling when the dot size is less than 10 nm. High-spin states are easily realized by applying a small magnetic field. This is quite different from the case of single-valley artificial atoms of GaAs quantum dots, where high spins appear due to the exchange interaction only in the case of orbital degeneracy (Hund's rule). When the dot size is much larger than 10 nm, the electron-electron interaction becomes relevant in determining the electronic states. Electrons are accommodated in a valley, making the highest spin, to gain the exchange energy.

We also investigate the effects of anisotropic shape of quantum dots and intervalley scattering. The former tends to make higher spins, whereas the latter could make lower spins. These spin states in multivalley artificial atoms should be observed by looking at the magnetic-field dependence of the peak positions in the Coulomb oscillation. We calculate the addition energies, as functions of the magnetic field, which correspond to the peak positions in the Coulomb oscillation.

The organization of the present paper is as follows. In the next section (Sec. II), we explain our model for Si quantum dots and calculation method using the effective mass approximation. In Sec. III, we present the calculated results for the electronic states in isotropic Si quantum dots. We discuss the fundamental properties of multivalley artificial atoms, with changing the size of the dots. In Sec. IV, we examine anisotropic Si quantum dots. In Sec. V, effects of intervalley scattering on the electronic states are considered. The last section (Sec. VI) is devoted to our conclusions and discussion.

II. MODEL AND CALCULATION METHOD

For the multivalley structure of conduction band in Si, we assume that two valleys at $\mathbf{k} = (0, 0, \pm k_0)$, where $k_0 = 0.85 \times 2\pi/a$ (a is the lattice constant, 0.357 nm), are equivalent and located below the other valleys at $\mathbf{k} = (\pm k_0, 0, 0)$ and $(0, \pm k_0, 0)$ by ΔE_{valley} . $\Delta E_{\text{valley}} = 100$

meV, considering the effect of oxidation-induced strain.^{11,21} The valleys of $\mathbf{k} = (0, 0, \pm k_0)$, $(\pm k_0, 0, 0)$, and $(0, \pm k_0, 0)$ are denoted by $\pm k_z$, $\pm k_x$, and $\pm k_y$ hereafter.

As a model for the confinement potential of quantum dots, we adopt a three-dimensional harmonic potential $V(x, y, z)$. We examine an isotropic confinement

$$V(x, y, z) = \frac{1}{2}K(x^2 + y^2 + z^2), \quad (1)$$

to focus on generic properties of electronic states in Si dots, for a while. An anisotropic confinement is studied later (Sec. IV).

First, we calculate one-electron states and energy levels in the absence of electron-electron interaction. In the effective mass approximation,²⁰ the wavefunction for electrons around a valley, e.g., $\pm k_z$, is described by a product of the Bloch wave at the valley and the envelope function $F_{\pm k_z}$

$$\psi_{\pm k_z}(\mathbf{r}) = F_{\pm k_z}(\mathbf{r})e^{\pm i\mathbf{k}_z \cdot \mathbf{r}}u_{\pm k_z}(\mathbf{r}), \quad (2)$$

where $\mathbf{k}_z = (0, 0, k_0)$ and $u_{\pm k_z}(\mathbf{r})$ is a function with the periodicity of the Bravais lattice. The envelope function $F_{\pm k_z}$ satisfies the effective mass equation

$$\begin{aligned} & \left[-\frac{\hbar^2}{2m_t^*} \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right) - \frac{\hbar^2}{2m_l^*} \frac{\partial^2}{\partial z^2} + V(x, y, z) \right] F_{\pm k_z}(\mathbf{r}) \\ &= \varepsilon F_{\pm k_z}(\mathbf{r}), \end{aligned} \quad (3)$$

where the energy ε is measured from the bottom of conduction band at $\pm k_z$. [In the effective mass equation around the valley of $\pm k_x$ ($\pm k_y$), m_l^* appears in the differential term with respect to x (y).] We disregard the interband scattering on the assumption that the confinement potential $V(x, y, z)$ is so smooth that its Fourier components with $k \sim 1/a$ are negligibly small. (The effect of interband scattering, which may stem from impurities within the dots, sharp edges of the dots, etc., is discussed in Sec. V.) Using $V(x, y, z)$ in Eq. (1), Eq. (3) yields the eigenvalues of

$$\begin{aligned} & \varepsilon(\pm k_z; n_x, n_y, n_z) \\ &= \hbar \sqrt{\frac{K}{m_t^*}} \left(n_x + \frac{1}{2} \right) + \hbar \sqrt{\frac{K}{m_t^*}} \left(n_y + \frac{1}{2} \right) + \hbar \sqrt{\frac{K}{m_l^*}} \left(n_z + \frac{1}{2} \right), \end{aligned} \quad (4)$$

with $n_x, n_y, n_z = 0, 1, 2, \dots$. [For valleys of $\pm k_x$ ($\pm k_y$), m_l^* appears in the first (second) term.] The eigenfunction for the lowest level with $(n_x, n_y, n_z) = (0, 0, 0)$ is given by

$$F_{\pm k_z}^{0,0,0}(\mathbf{r}) = \left(\frac{1}{\pi\hbar}\right)^{\frac{3}{4}} (m_t^{*2} m_l^* K^3)^{\frac{1}{8}} \times \exp \left[-\frac{1}{2\hbar} (\sqrt{m_t^* K} x^2 + \sqrt{m_t^* K} y^2 + \sqrt{m_l^* K} z^2) \right]. \quad (5)$$

The size of the confinement potential is given by

$$l = 2\sqrt{\hbar/m_t^* \omega_t}, \quad (6)$$

where $\omega_t = \sqrt{K/m_t^*}$, using the smaller effective mass m_t^* . Three cases of $l = 5$ nm, 10 nm, and 15 nm are examined.

Many-body states are simply represented by single configuration of the occupation of the one-electron levels by N electrons, for semi-quantitative discussion. The Coulomb and exchange interactions between electrons $(k_i; n_x, n_y, n_z)$ and $(k_j; n'_x, n'_y, n'_z)$ are written as

$$\begin{aligned} & \int \int d\mathbf{r}_1 d\mathbf{r}_2 |\psi_{k_i}^{n_x, n_y, n_z}(\mathbf{r}_1)|^2 \frac{e^2}{4\pi\epsilon |\mathbf{r}_1 - \mathbf{r}_2|} |\psi_{k_j}^{n'_x, n'_y, n'_z}(\mathbf{r}_2)|^2 \\ &= \int \int d\mathbf{r}_1 d\mathbf{r}_2 |F_{k_i}^{n_x, n_y, n_z}(\mathbf{r}_1)|^2 \frac{e^2}{4\pi\epsilon |\mathbf{r}_1 - \mathbf{r}_2|} |F_{k_j}^{n'_x, n'_y, n'_z}(\mathbf{r}_2)|^2 \end{aligned} \quad (7)$$

and

$$\begin{aligned} & \int \int d\mathbf{r}_1 d\mathbf{r}_2 \psi_{k_i}^{n_x, n_y, n_z*}(\mathbf{r}_1) \psi_{k_j}^{n'_x, n'_y, n'_z*}(\mathbf{r}_2) \\ & \times \frac{e^2}{4\pi\epsilon |\mathbf{r}_1 - \mathbf{r}_2|} \psi_{k_j}^{n'_x, n'_y, n'_z}(\mathbf{r}_1) \psi_{k_i}^{n_x, n_y, n_z}(\mathbf{r}_2) \\ &= \int \int d\mathbf{r}_1 d\mathbf{r}_2 e^{i(\mathbf{k}_j - \mathbf{k}_i) \cdot \mathbf{r}_1} e^{i(\mathbf{k}_i - \mathbf{k}_j) \cdot \mathbf{r}_2} \frac{e^2}{4\pi\epsilon |\mathbf{r}_1 - \mathbf{r}_2|} \\ & \times F_{k_i}^{n_x, n_y, n_z*}(\mathbf{r}_1) F_{k_j}^{n'_x, n'_y, n'_z*}(\mathbf{r}_2) F_{k_j}^{n'_x, n'_y, n'_z}(\mathbf{r}_1) \\ & \times F_{k_i}^{n_x, n_y, n_z}(\mathbf{r}_2) u_{k_i}^*(\mathbf{r}_1) u_{k_j}^*(\mathbf{r}_2) u_{k_j}(\mathbf{r}_1) u_{k_i}(\mathbf{r}_2), \end{aligned} \quad (8)$$

respectively, with dielectric constant $\epsilon = 11.9\epsilon_0$. These terms are evaluated numerically. We calculate the total energy for all possible configurations and determine the ground state.

In a magnetic field $\mathbf{B} = (0, 0, B)$, we consider the Zeeman energy

$$E_{\text{Zeeman}} = -g^* \mu_B S_{\text{tot}, z} B, \quad (9)$$

where $g^* = 2$, μ_B is the Bohr magneton, and $S_{\text{tot},z}$ is the z component of the total spin. The orbital magnetization effect is disregarded because of large effective mass in Si.²²

III. ELECTRONIC STATES IN SI QUANTUM DOTS

In this section, we clarify the basic properties of electronic states in Si quantum dots, considering an isotropic confinement, Eq. (1).

A. Electronic states

We begin with the one-electron energy levels. As shown in Eq. (4), the one-electron levels are labeled by valley index and quantum numbers (n_x, n_y, n_z) for the orbital motion. The lowest levels belong to the valleys of $+k_z$ or $-k_z$ with $(n_x, n_y, n_z) = (0, 0, 0)$ (see horizontal lines in Fig. 1). The next levels are $(\pm k_z; 0, 0, 1)$, which are lower than levels $(\pm k_z; 1, 0, 0)$ and $(\pm k_z; 0, 1, 0)$ in spite of the isotropic confinement. This is due to the anisotropy of the effective mass [$\varepsilon(\pm k_z; 1, 0, 0) - \varepsilon(\pm k_z; 0, 0, 1) = \hbar(\sqrt{K/m_t^*} - \sqrt{K/m_l^*})$]. We find that all the electrons are accommodated in valleys of $\pm k_z$ for $N = 1$ to 5 in all the cases of the dot size.

Regarding the electron-electron interaction between different valleys, we obtain two significant results. (i) The Coulomb interaction between $(\pm k_z; n_x, n_y, n_z)$ and $(\pm k_z; n'_x, n'_y, n'_z)$ is the same as that between $(\pm k_z; n_x, n_y, n_z)$ and $(\mp k_z; n'_x, n'_y, n'_z)$. This is because the envelope functions are equivalent for the valleys of $+k_z$ and $-k_z$ in Eq. (7). (ii) The exchange interaction is negligibly small between electrons in different valleys, owing to the integration of rapidly oscillating factors in Eq. (8). Therefore, there is no spin coupling (Hund's coupling) between different valleys.

When the dot size is $l = 5$ nm or 10 nm, two electrons occupy the lowest level in different valleys in the absence of Hund's coupling. In consequence, the energies of different spin states are degenerate. The configuration in Fig. 1(a₁) has the total spin of $S_{\text{tot}} = 0$, whereas that in Fig. 1(a₂) has $S_{\text{tot}} = 1/2 \otimes 1/2 = 0 \oplus 1$. These configurations have the same energy. In a small magnetic field, the Zeeman effect, Eq. (9), makes the largest spin of $S_{\text{tot}} = 1$ with $S_{\text{tot},z} = 1$.

When the dot size is $l = 15$ nm, the ground state with $N = 2$ has another configuration; one electron occupies an upper level to gain the exchange energy with the other electron

with parallel spin in a valley [Fig. 1(b)]. Note that the exchange interaction, Eq. (8), works effectively between electrons only in the same valley. In general, the electronic states are determined by the competition between the electron-electron interaction and spacing of one-electron energy levels. When the dot size is l , the former is characterized by $E_{\text{int}} = e^2/(4\pi\epsilon l)$, whereas the latter is by $E_{\text{levels}} = \hbar^2/(m_t^* l^2)$. The ratio of these energies, $E_{\text{int}}/E_{\text{levels}} = m_t^* e^2 l / (4\pi\epsilon \hbar^2)$, is 1.52, 3.04, and 4.56 for $l = 5$ nm, 10 nm, and 15 nm, respectively. When the ratio is larger, more electrons are accommodated in a valley with parallel spins to gain the exchange energy.

The ground state with $N = 3$, shown in Fig. 2, can be understood in a similar way. For the smallest dot ($l = 5$ nm), three electrons occupy the lowest levels [$S_{\text{tot}} = 1/2$; Fig. 2(a)]. For the largest dot ($l = 15$ nm), they occupy upper levels in a valley, making $S_{\text{tot}} = 3/2$, to gain the exchange energy [Fig. 2(b)]. For the intermediate case ($l = 10$ nm), two electrons make a spin triplet, occupying two levels in a valley, while an electron is accommodated in the lowest level in the same valley (c_1) or in the other equivalent valley (c_2). These configurations have the same energy but different spin, (c_1) $S_{\text{tot}} = 1/2$ and (c_2) $S_{\text{tot}} = 1 \otimes 1/2 = 1/2 \oplus 3/2$, the largest spin of which is realized in a magnetic field.

With increasing magnetic field, the Zeeman effect, Eq. (9), makes larger spin states more favorable. For $N = 3$, the ground state could change from configuration Fig. 2(a) ($S_{\text{tot}} = 1/2$) at $B < B_c$ to configuration Fig. 2(b) ($S_{\text{tot}} = 3/2$) at $B > B_c$. Such a transition is observed at $B_c = 9.47$ T when the dot size is $l = 7.5$ nm. (The same transition takes place at much larger B_c when $l = 5$ nm.) We find a similar transition with $N = 4$, from $S_{\text{tot}} = 1$ to $S_{\text{tot}} = 2$ at $B_c = 3.44$ T, when the dot size is $l = 7.5$ nm.

B. Addition energies

For the comparison with the experimental results, we calculate addition energies which correspond to peak positions of the Coulomb oscillation.^{1,2} The addition energy of the N th electron on the dot is given by

$$\mu_N = E_N - E_{N-1}, \quad (10)$$

where E_N is the ground-state energy with N electrons. Figure 3 shows μ_N ($N = 1$ to 5), as functions of magnetic field B . The slope of $\mu_N(B)$ is given by

$$-g^* \mu_B [S_{\text{tot}}(N) - S_{\text{tot}}(N-1)],$$

which reflects the total spin $S_{\text{tot}}(N)$ with N electrons.

In Fig. 3(a), the dot size is the smallest ($l = 5$ nm). The one-electron levels are consecutively occupied with increasing the number of electrons N . For $N = 2$, the electrons are accommodated in different valleys with parallel spins in a magnetic field, as discussed previously. In consequence, $S_{\text{tot}}(N) = 1/2, 1, 1/2, 0$, and $1/2$ for $N = 1$ to 5, respectively. This results in the slope of $-g^* \mu_B/2$ for $\mu_1(B)$, $\mu_2(B)$, $\mu_5(B)$, and $+g^* \mu_B/2$ for $\mu_3(B)$, $\mu_4(B)$.

In Fig. 3(b), the dot is the largest ($l = 15$ nm). To gain the exchange energy, the electrons occupy upper levels in a valley, making the highest spin, $S_{\text{tot}}(N) = N/2$. Accordingly, $\mu_N(B)$ ($N = 1$ to 5) are parallel to each other, with the same slope of $-g^* \mu_B/2$. When the dot size is $l = 10$ nm, the highest spin of $S_{\text{tot}}(N) = N/2$ is also realized. The slopes of $\mu_N(B)$ ($N = 1$ to 5) are the same as those in Fig. 3(b).

In Fig. 3(c), the dot size is $l = 7.5$ nm. $\mu_3(B)$ shows a kink at $B_c = 9.47$ T, which is due to the transition of the ground state with $N = 3$ from $S_{\text{tot}}(3) = 1/2$ to $3/2$. Since $S_{\text{tot}}(2) = 1$, the slope of $\mu_3(B)$ is $g^* \mu_B/2$ and $-g^* \mu_B/2$ at $B < B_c$ and $B > B_c$, respectively. This transition results in a kink of $\mu_4(B)$ at the same magnetic field [with $S_{\text{tot}}(4) = 2$, the slope of $\mu_4(B)$ is $-3g^* \mu_B/2$ at $B < B_c$, $-g^* \mu_B/2$ at $B > B_c$]. Similarly, the transition of the ground state with $N = 4$ makes a pair of kinks on $\mu_4(B)$ and $\mu_5(B)$ at $B_c = 3.44$ T. Such pairs of kinks of adjacent addition energies have been observed in the Coulomb oscillation.¹⁴

At $3.44 \text{ T} < B < 9.47 \text{ T}$ in Fig. 3(c), $\mu_4(B)$ has a slope of $-3g^* \mu_B/2$ (indicated by dotted line). Then the conductance through the quantum dot should be suppressed since the addition of the fourth electron is forbidden by the spin selection rule: $S_{\text{tot}} = 1/2$ with $N = 3$ and $S_{\text{tot}} = 2$ with $N = 4$. This is called spin blockade.²³ The spin blockade in Si quantum dots has been found experimentally.¹⁴

IV. ANISOTROPIC CONFINEMENT

In the previous section, we have examined the isotropic confinement to illustrate the basic properties of Si quantum dots. In this section, we investigate an anisotropic con-

finement. Quantum dots, which are fabricated in the middle of Si wires with oxidation technique,^{10,11,12,14,15,16} may be elongated along the wires. We adopt an elliptical potential, elongated in $[110]$ direction of the lattice,¹¹

$$V(x, y, z) = \frac{1}{2} \left[K' \left(\frac{x+y}{\sqrt{2}} \right)^2 + K \left(\frac{-x+y}{\sqrt{2}} \right)^2 + Kz^2 \right]. \quad (11)$$

with $K' < K$. By the transformation of the axes to $X = (x+y)/\sqrt{2}$, $Y = (-x+y)/\sqrt{2}$, and z , it is rewritten as $V(X, Y, z) = (1/2)(K'X^2 + KY^2 + Kz^2)$. For valleys of $\pm k_z$, the one-electron energy levels are given by

$$\begin{aligned} \varepsilon(\pm k_z; n_X, n_Y, n_z) \\ = \hbar \sqrt{\frac{K'}{m_t^*}} \left(n_X + \frac{1}{2} \right) + \hbar \sqrt{\frac{K}{m_t^*}} \left(n_Y + \frac{1}{2} \right) + \hbar \sqrt{\frac{K}{m_l^*}} \left(n_z + \frac{1}{2} \right). \end{aligned} \quad (12)$$

We change the size of the confinement potential in $[110]$ direction, $l_X = 2\sqrt{\hbar/m_t^*\omega_{Xt}}$ where $\omega_{Xt} = \sqrt{K'/m_t^*}$, as 5 nm, 10 nm, and 15 nm. The size in $[\bar{1}10]$ and $[001]$ directions is fixed at $l_Y = l_z = 5$ nm, where $l_Y = 2\sqrt{\hbar/m_t^*\omega_{Yt}}$, and $l_z = 2\sqrt{\hbar/m_t^*\omega_{zt}}$ with $\omega_{Yt} = \omega_{zt} = \sqrt{K/m_t^*}$.

Figure 4 shows the electronic configuration of the ground state with $N = 4$ when (a) $l_X = 5$ nm (isotropic dot), (b) $l_X = 10$ nm, and (c) 15 nm. As the shape of the dot is more elongated in $[110]$ direction, the energy levels $(n_X, 0, 0)$ ($n_X = 1, 2, 3 \dots$) are lowered [see Eq. (12) with smaller K']. Electrons begin to occupy these levels: (a) $(\pm k_z; 0, 0, 0)$ only, (b) $(\pm k_z; 0, 0, 0)$ and $(\pm k_z; 1, 0, 0)$, and (c) $(0, 0, 0)$ to $(3, 0, 0)$ in a valley. This means that the electrons tend to be populated in the elongated direction. Reflecting small level spacings between $(n_X, 0, 0)$, high-spin states are realized more often: (a) $S_{\text{tot}} = 0$, (b) $S_{\text{tot}} = 1 \otimes 1 = 0 \oplus 1 \oplus 2$, and (c) $S_{\text{tot}} = 2$. We find that the ground state has the largest spin of $S_{\text{tot}}(N) = N/2$ for $N = 1$ to 5 in elongated dots with $l_X = 10$ nm and 15 nm ($l_Y = l_z = 5$ nm) in a magnetic field. The magnetic-field dependence of addition energies μ_N shows the same slope of $-g^*\mu_B/2$, which is similar to the situation in Fig. 3(b).

V. INTERVALLEY SCATTERING

In the present section, we discuss the effects of intervalley scattering. The intervalley scattering is not relevant when the size of the dots is much larger than the lattice constant

and confinement potential is sufficiently smooth. However, the scattering by impurities within the dots, sharp edges of the dots, etc., mixes the electronic states in different valleys. As an example, let us consider an impurity potential at $\mathbf{R}$ inside a quantum dot,

$$V_{\text{imp}}(\mathbf{r}) = V_0 \delta(\mathbf{r} - \mathbf{R}),$$

to the lowest order of the perturbation. The degenerate levels of $(\pm k_z; n_x, n_y, n_z)$ are split into two by this potential,

$$\varepsilon(a; n_x, n_y, n_z) = \varepsilon(\pm k_z; n_x, n_y, n_z),$$

and

$$\varepsilon(b; n_x, n_y, n_z) = \varepsilon(\pm k_z; n_x, n_y, n_z) + \Delta_{n_x, n_y, n_z},$$

where $\Delta_{n_x, n_y, n_z} = 2V_0 |F_{\pm k_z}^{n_x, n_y, n_z}(\mathbf{R})|^2 |u_{\pm k_z}(\mathbf{R})|^2$, as shown in Fig. 5(a). The corresponding wavefunctions are expressed as

$$\begin{aligned} \psi_a^{n_x, n_y, n_z}(\mathbf{r}) &= \frac{1}{\sqrt{2}} \{ \psi_{+k_z}^{n_x, n_y, n_z}(\mathbf{r}) - e^{-i\theta} \psi_{-k_z}^{n_x, n_y, n_z}(\mathbf{r}) \}, \\ \psi_b^{n_x, n_y, n_z}(\mathbf{r}) &= \frac{1}{\sqrt{2}} \{ \psi_{+k_z}^{n_x, n_y, n_z}(\mathbf{r}) + e^{-i\theta} \psi_{-k_z}^{n_x, n_y, n_z}(\mathbf{r}) \}, \end{aligned}$$

with $\theta = \arg\langle +k_z; n_x, n_y, n_z | V_{\text{imp}} | -k_z; n_x, n_y, n_z \rangle$. For the electron-electron interactions, we find that (i) the Coulomb interaction between $(a; n_x, n_y, n_z)$ and $(a; n'_x, n'_y, n'_z)$ is identical to that between $(b; n_x, n_y, n_z)$ and $(b; n'_x, n'_y, n'_z)$, and also to that between $(a; n_x, n_y, n_z)$ and $(b; n'_x, n'_y, n'_z)$. (ii) The exchange interaction is negligibly small between $(a; n_x, n_y, n_z)$ and $(b; n'_x, n'_y, n'_z)$.

The intervalley scattering influences the spin states in a spherical dot of $l = 5$ nm. In the absence of intervalley scattering, the first two electrons occupy the degenerate levels of $(\pm k_z; 0, 0, 0)$ with parallel spins [$S_{\text{tot}}(2) = 1$] in a small magnetic field [Fig. 1(a₂)]. In the presence of intervalley scattering, the two electrons occupy the lowest level of $(a; 0, 0, 0)$ with anti-parallel spins [$S_{\text{tot}}(2) = 0$], as shown in Fig. 5(a). For $N = 1$ to 5, the spin states become $S_{\text{tot}}(N) = 1/2, 0, 1/2, 0$, and $1/2$, respectively.

The addition energies are shown in Fig. 5(b), as functions of magnetic field, in the case of $\Delta_{0,0,0} = 2$ meV. The slopes of μ_N are $-g^* \mu_B/2$ or $+g^* \mu_B/2$ alternately with increasing N , reflecting the above-mentioned spin states. In the case of $\Delta_{0,0,0} = 0.4$ meV, the transition of the ground state with $N = 2$ is observed at the magnetic field of $B_c = 3.45$ T, where

$g^*\mu_B B_c = \Delta_{0,0,0}$. For $B < B_c$, two electrons occupy level $(a; 0, 0, 0)$, making $S_{\text{tot}}(2) = 0$, as shown in Fig. 5(a). For $B > B_c$, one electron occupies level $(a; 0, 0, 0)$ and the other occupies level $(b; 0, 0, 0)$ with parallel spins [$S_{\text{tot}}(2) = 1$], to gain the Zeeman energy. This transition makes a pair of kinks on μ_2 and μ_3 [see Fig. 5(c)].

When the dot size is much larger than 10 nm, the intervalley scattering never changes the spin states. Electrons occupy the levels of $(a; 0, 0, 0)$, $(a; 0, 0, 1)$, $(a; 1, 0, 0)$, $\dots$, consecutively with parallel spins to gain the exchange energy [not the levels of $(b; n_x, n_y, n_z)$ owing to the absence of exchange interactions between $(b; n_x, n_y, n_z)$ and $(a; n'_x, n'_y, n'_z)$]. Then the largest spins of $S_{\text{tot}}(N) = N/2$ are realized. The addition energies $\mu_N(B)$ ($N = 1$ to 5) have the same slope of $-g^*\mu_B/2$, in the same way as in Fig. 3(b).

VI. CONCLUSIONS AND DISCUSSION

We have theoretically examined the electronic states in Si dots, multivalley artificial atoms. (i) In spherical quantum dots smaller than ~ 10 nm, the one-electron levels in equivalent valleys are occupied consecutively with increasing the number of electrons N . High-spin states are attributable to the absence of spin couplings between different valleys. This is quite different from the case of GaAs quantum dots, where high spins appear due to the exchange interaction in exceptional cases with orbital degeneracy (Hund's rule). (ii) In quantum dots much larger than 10 nm, the electrons tend to occupy upper levels in a valley, making the largest spin of $S_{\text{tot}} = N/2$, to gain the exchange energy. (iii) In elliptical quantum dots, the electrons tend to be populated in the elongated direction. High-spin states often appear. (iv) In the presence of intervalley scattering, the degenerate energy levels in different valleys are split. In small dots, this results in the lowest spin states ($S_{\text{tot}} = 0$ or $1/2$). The spin states in large dots, $S_{\text{tot}} = N/2$, are not influenced by the intervalley scattering.

In the present study, the electronic states are represented by single configurations of the occupation of one-electron levels by N electrons, for semi-quantitative discussion. We have neglected the configuration interaction, or correlation effect. (It should be noted that the configuration interaction vanishes between electrons in different valleys for the same reason as the exchange interaction vanishes.) In this approximation, the energy of low-spin states is overestimated compared with the energy of high-spin states. Hence we should have underestimated the dot size where the highest spins appear. The correlation effect becomes

more important as the dot size is larger ($E_{\text{int}}/E_{\text{levels}}$ is larger) for quantitative discussion.⁹ The consideration of the correlation effect with multivalley structure in Si dots requires further study.

The spin states in Si quantum dots depend on both their size and shape. Our calculated results cannot be compared directly with experimental results of the Coulomb oscillation^{14,15,16} since the exact shape of quantum dots is not known. Roughly speaking, the magnetic-field dependence of peak positions in the observed Coulomb oscillation is similar to that in Figs. 5(b), (c) rather than that in Figs. 3(a)-(c), which might imply that low-spin states are realized in small dots and in the presence of intervalley scattering. Qualitatively, pairs of kinks have been observed,¹⁴ which indicate the transitions of the ground state. The spin blockade with $|S_{\text{tot}}(N+1) - S_{\text{tot}}(N)| \geq 3/2$ has also been reported.¹⁴ We have shown that the spin states can be changed by the intervalley scattering. If the strength of the intervalley scattering were tuned, e.g., using STM tips, the spin states in Si dots could be controlled.

Recently, quantum computing devices have been proposed, utilizing electron spins in quantum dots.¹⁹ For the devices, the decoherence time of electron spins must be much longer than the gate operation time. Main origins of the decoherence are spin-orbit interaction and hyperfine interaction with nuclear spins in the dots. In Si, the spin-orbit interaction is much weaker than in GaAs. The hyperfine interaction is also weaker due to smaller isotope ratio with nuclear spins (²⁹Si of 4.7% only). Hence a longer decoherence time is expected in Si quantum dots than in GaAs quantum dots. Therefore, Si dots may be advantageous to the quantum computing devices. In Si dots, high-spin states are realized easily, which could be utilized for the devices.

FIG. 1: Electronic configurations for the ground state with $N = 2$ in isotropic quantum dots. (n_x, n_y, n_z) are the orbital quantum numbers for each one-electron level, whereas $\pm k_z$ are the valley indices. Configuration (a₁) or (a₂) is realized when the dot size is $l = 5$ and 10 nm. They are degenerate in energy in the absence of magnetic field. The total spin is $S_{\text{tot}} = 0$ and $S_{\text{tot}} = 1/2 \otimes 1/2 = 0 \oplus 1$, respectively. Configuration (b) with $S_{\text{tot}} = 1$ is realized for $l = 15$ nm.

FIG. 2: Electronic configurations for the ground state with $N = 3$ in isotropic quantum dots. (n_x, n_y, n_z) are the orbital quantum numbers for each one-electron level, whereas $\pm k_z$ are the valley indices. Configurations (a) and (b) are realized when the dot size is $l = 5$ nm and 15 nm, respectively. Configuration (c₁) or (c₂) appears for $l = 10$ nm. When the dot size is $l = 7.5$ nm, configuration (a) appears at $B < 9.47$ T, whereas (c₂) appears $B > 9.47$ T.

FIG. 3: Addition energies, μ_N ($N = 1$ to 5), as functions of magnetic field B , in isotropic quantum dots. The dot size is (a) $l = 5$ nm, (b) 15 nm, and (c) 7.5 nm. In (c), the spin blockade occurs for $\mu_4(B)$ at $3.44 \text{ T} < B < 9.47 \text{ T}$ (dotted line).

FIG. 4: Electronic configurations for the ground state with $N = 4$ in elliptical quantum dots. (n_X, n_Y, n_z) are the orbital quantum numbers for each one-electron level, whereas $\pm k_z$ are the valley indices. The size of the dot in $[110]$ direction is (a) $l_X = 5$ nm, (b) 10 nm, and (c) 15 nm, whereas the size in the other directions is fixed at $l_Y = l_z = 5$ nm.

FIG. 5: (a) The effect of intervalley scattering on the one-electron energy levels. The degenerate levels of $(\pm k_z; n_x, n_y, n_z)$ are split into two. (b), (c) Addition energies, μ_N ($N = 1$ to 5), as functions of magnetic field B , in isotropic quantum dots of $l = 5$ nm. The energy splitting by the intervalley scattering is (b) $\Delta_{0,0,0} = 2$ meV and (c) $\Delta_{0,0,0} = 0.4$ meV.
